Climate change has led to major changes in the phenology (the timing of seasonal activities, such as flowering) of some species but not others. The extent to which flowering-time response to temperature is shared among closely related species might have important consequences for community-wide patterns of species loss under rapid climate change. Henry David Thoreau initiated a dataset of the Concord, Massachusetts, flora that spans ≈ 150 years and provides information on changes in species abundance and flowering time. When these data are analyzed in a phylogenetic context, they indicate that change in abundance is strongly correlated with flowering-time response. Species that do not respond to temperature have decreased greatly in abundance, and include among others anemones and buttercups [*Ranunculaceae pro parte (p.p.)*], asters and campanulas (*Asterales*), bluets (*Rubiaceae p.p.*), bladderworts (*Lentibulariaceae*), dogwoods (*Cornaceae*), lilies (*Liliales*), mints (*Lamiaceae p.p.*), orchids (*Orchidaceae*), roses (*Rosaceae p.p.*), saxifrages (*Saxifragales*), and violets (*Malpighiales*). Because flowering-time response traits are shared among closely related species, our findings suggest that climate change has affected and will likely continue to shape the phylogenetically biased pattern of species loss in Thoreau's woods.

conservation | extinction | phenology | phylogenetic conservatism | phylogeny

The impact of climate change on species and communities has been well documented. Arctic forests are shifting poleward and alpine tree lines are shifting upward (1–3); spring flowering time is advancing rapidly (4–7); pest outbreaks are spreading (8); and numerous species are declining in abundance and risk extinction (9). However, despite these generalized trends, species vary dramatically in their responses to climate change. For example, although the spring flowering times of many temperate plants are advancing, some are not changing and others are flowering later in the season (5, 10, 11). Understanding the evolutionary (i.e., phylogenetic) history of traits that are influenced by climate (e.g., flowering phenology) has been an underexplored area of climate change biology, despite the fact that it could prove especially useful in predicting how species and communities will respond to future climate change. Closely related species often share similar traits, a pattern known as phylogenetic conservatism (12–16, 17). If closely related species share similar traits that make them more susceptible to climate change (14, 17), species loss may not be random or uniform, but rather biased against certain lineages in the Tree of Life (i.e., phylogenetic selectivity; see ref. 18). However, a deeper inquiry into these patterns has been hampered largely because adequate datasets documenting community-wide responses to climate change are exceedingly rare.

During the mid-19th century, the naturalist and conservationist Henry David Thoreau spent decades exploring the temperate fields, wetlands, and deciduous forests of Concord, Massachusetts, in the northeastern United States. He wrote extensively about the natural history of the area (19) and kept meticulous notes on plant species occurrences and flowering times (11, 20). Several botanists have since resurveyed the Concord area, thus

providing a unique community-level perspective on changes in its floristic composition and flowering times during the past ≈ 150 years (11, 20). Despite the fact that $\approx 60\%$ of all natural areas in Concord are undeveloped or have remained well protected, a striking number of species have become locally extinct: 27% of the species documented by Thoreau have been lost, and 36% exist in such low population abundances that their extirpation may be imminent (20). Also, the species that have been lost are overly represented in particular plant families (20), suggesting that extinction risk may be phylogenetically biased.

Although habitat loss due to succession and development (e.g., loss of wetlands, abandonment of farms, reforestation, and construction of homes and roads) has contributed to decreases in abundance for some species in Thoreau's Concord (20), climate change may also help to explain the seemingly nonrandom pattern of species loss among certain plant groups. It has been shown recently (11) that the mean annual temperature in the Concord area has risen by 2.4 °C over the past ≈ 100 years and that this temperature change is associated with shifts in flowering time: species are now flowering an average of 7 days earlier than in Thoreau's time. Along with changes in flowering phenology, species range is likely to be influenced by climate change (21). Thus, the Concord surveys provide a unique opportunity to examine the extent to which changes in abundance may be correlated with these climatologically sensitive traits. Also, by incorporating phylogenetic history into our analyses, we can test whether species that share similar traits are closely related (i.e., phylogenetic conservatism), and to what extent these traits correlate with decreases in abundance. Such findings could identify groups of closely related species that are at higher risk of extinction (18, 22).

The data for the 473 species we analyzed were collected by Thoreau (1852–1858), Hosmer (1878, 1888–1902), and Miller-Rushing and Primack (2003–2007) (see *Materials and Methods*; see refs. 20 and 23). Scorings include information on changes in species abundance, species habitat, and 2 separate measures of flowering-time response to temperature (i.e., the ability of species flowering time to track short-term seasonal temperature changes, and the shift in species flowering time over long-term intervals). We further scored the current mean latitudinal range and native/introduced status of each species. We constructed a composite phylogeny of all species to test for: (i) the phylogenetic conservatism of each trait, and (ii) correlations between these traits and change in abundance when accounting for phylogeny.

Fig. 1. Composite phylogeny of 429 flowering plant species from the Concord flora depicting changes in abundance from 1900 to 2007. Change in abundance ranged on an integer scale from -5 to $+4$, and was calculated as the difference in abundance for each taxon in 1900 and 2007 based on 7 abundance categories (0 to 6; see *Materials and Methods*). Branch color indicates parsimony character state reconstruction of change in abundance. For simplicity, we have indicated this reconstruction by using 4 colors: red (major decline, -5 to -3), pink (moderate decline, -2), gray (little to no change, -1 to $+1$), and blue (increase, $+2$ to $+4$). For the complete character reconstruction and taxon labels see [Fig. S1](#). Average decline in abundance was calculated for all internal nodes as the mean change in abundance of descendant nodes weighted with branch length information ascertained from divergence time estimates. An average decline of 2.5 or greater corresponds to a decline in abundance of 50% or greater, based on our most conservative scoring using 6 abundance categories (0 to 5; see *Materials in Methods*). Clades exhibiting these major declines are indicated with black dots. Each of the most inclusive clades exhibiting these declines are indicated in pink and referenced numerically to their clade name. Subclades in major decline that are nested within more widely recognized clades are labeled with the more familiar name followed by *pro parte* (*p.p.*). These clades include some of the most charismatic wildflower species in New England, such as anemones and buttercups (Ranunculaceae *p.p.*), asters, campanulas, goldenrods, pussytoes, and thistles (Asterales), bedstraws and bluets (Rubiaceae *p.p.*), bladderworts (Lentibulariaceae), dogwoods (Cornaceae), lilies (Liliales), louseworts and Indian paintbrushes (Orobanchaceae), mints (Lamiaceae *p.p.*), orchids (Orchidaceae), primroses (Onoagraceae *p.p.*), roses (Rosaceae *p.p.*), saxifrages (Saxifragaales), Indian pipes (Ericales *p.p.*), and St. John's worts and violets (Malpighiales).

Results and Discussion

Our results (Fig. 1 and Table 1) indicate that change in abundance and flowering-time response traits were phylogenetically conserved, which indicates that species evolutionary history is important to understanding community response to

climate change. Species that are declining in abundance are more closely related than expected by chance. Similarly, species that exhibit similar flowering-time responses to temperature are more closely related than expected by chance. In contrast, latitudinal range was not phylogenetically conserved

Table 1. Statistical tests of phylogenetic conservatism and trait correlations with change in abundance

[illegible]

Tests used a phylogeny with branch lengths adjusted for time. The significance of phylogenetic conservatism was tested by comparing the rank of the observed standard deviation (SD) of descendent trait means to a null model based on 9,999 random iterations of trait distributions across the composite phylogeny. The observed rank is compared with a 2-tail test of significance, i.e., an observed rank of 250 equals a *P* value of 0.05. Trait correlations were tested by using the comparative methods of generalized estimating equations (GEE). Estimates describe the direction and magnitude of the correlation (e.g., a negative estimate [−0.1] of mean latitude with change in abundance suggests that species from more southerly latitudes are increasing in abundance). Model 1 (univariate model), correlation of change in abundance with each trait; Model 2 (multivariate model), correlation of change in abundance with each trait and habitat, abundance (ca. 1900), flowering season, and native/introduced status as covariates; Model 3 (multivariate model), correlation of change in abundance with all traits and habitat, abundance (ca. 1900), flowering season, and native/introduced status as covariates (shift in flowering-time response 1850–2006 was excluded due to its high correlation with the other flowering-time shift traits). †, *P* = 0.1; *, *P* = 0.05; **, *P* = 0.01; ***, *P* = 0.001; *n* = sample size.

Records from 1888 to 1902 included the following 6 abundance categories: Very common, common, frequent, infrequent, uncommon, and rare. Abundance categories from 2003 to 2007 were approximated to match the 1888–1902 survey by using Hosmer's journal records, and include: very common (found throughout the area), common (occurring in >3 localities), frequent (occurring in 3 localities), infrequent (occurring in 2 localities), rare (occur in 1 locality), and very rare (10 or less individuals in a single locality). These 6 abundance categories were treated as a continuous trait scored from high (6) to low (1) abundance, with an additional scoring of zero for any species absent from a given survey. We also analyzed these data with the categories very common and common combined (i.e., states 5 to 0). This more conservative scoring did not significantly affect our results (results not shown).

Change in abundance was defined as the difference in abundance between the 1888–1902 and 2003–2007 surveys; 44 taxa that were indicated as rare in 1900 and extinct in 2007 were excluded. Rare species are considerably more likely to go extinct by chance alone (24), and so might bias our results by inflating declines in abundance.

Habitat. Species were assigned to 1 of 5 habitat categories: forest, grassland and field, roadside, wetland, and aquatic. When species occurred in 2 or more habitats, they were assigned to the habitat where Eaton and Primack and Miller-Rushing saw the species most frequently (20). Habitat was included as a covariate in the models to control for the effect of habitat loss on extinction (see *Phylogenetic Conservatism and Trait Correlations* below). Importantly, species were lost from all habitats at approximately the same rate (20), which indicates that no habitat was particularly biased toward higher rates of extinction. This result, especially when considering the protected nature of the Concord area, indicates that these patterns of local extirpation cannot be simply explained by human development or succession.

Flowering-Time Response: Flowering-Time Tracking of Seasonal Temperature. The 15-year period between 1888 and 1902 provides the longest survey period to quantify the tracking of species flowering time with seasonal temperature. Flowering-time tracking was determined with regard to seasonal variation in winter temperature (average temperature over January, April, and May; see ref. 11). April and May represent monthly temperatures commonly associated with annual flowering in this region. The month of January was also included because it was found to correlate with the flowering time of many species. This correlation is presumably due to the severe cold of midwinter, which can damage plants and, thus, delay spring flowering (23). Flowering-time tracking was quantified as the correlation coefficient between annual first flowering day and winter temperature (11). Unlike flowering-time shift, our measure of flowering-time tracking from 1888 to 1902 is less likely to be affected by changes in abundance because population size was likely more stable during this shorter period (31). This trait provides an important measure of a species ability to respond to short-term temperature variation, allowing us to relate short-term temperature response with long-term changes in abundance from 1900 to 2006.

Flowering-Time Response: Shift in Flowering Time. First day of flowering was recorded by Thoreau, Hosmer, and Miller-Rushing and Primack for 465, 461, and 478 species, respectively. Observations were recorded annually for nearly all species over the duration of each botanists' survey (11). The timing of first flowering for each species was averaged over each botanists' survey period. Shift in first flowering day was calculated as the difference in mean first flowering day from 1850–1900, 1850–2007, and 1900–2007 (11).

Name Standardization. We standardized species names in the Concord flora by using the U.S. Department of Agriculture PLANTS Database (45). The most current accepted species name recognized in the database was used as our "correct" species name. This standardized taxonomy was then used in all downstream applications including species range estimation and phylogenetic tree construction (see below). In a small number of cases (18 species), sister species were identified as synonyms. These sister taxa were collapsed into a single taxon.

Species Latitudinal Range Estimation. The latitudinal data of species were compiled from several online databases including: the U.S. Department of Agriculture PLANTS Database, the National Herbarium of Canada, the Canadian Biodiversity Information Facility, the Royal Botanic Gardens Kew, Fairchild Tropical Botanic Garden, and the Missouri Botanical Garden (TROPICOS). Latitudinal data in these databases were derived from the literature, field-based observations, and herbarium specimens. In total, 384,292 data points were obtained for 530 species with a median of 608 observations per species. Three species with <20 observations were not included in the analysis due to

the paucity of data. The average latitude for each species was obtained across the contiguous United States and adjacent Canada. The mean latitude for each species was weighted by the number of observations across the range, which more accurately represents the latitudinal affinity of each species.

Local declines in abundance could be due to populations occurring at the edge of their ranges, and thus their environmental tolerances. Alternatively, if climate change is shifting environments northward, we would expect species with a range edge more north of Concord to be declining in abundance. We tested for the effect of species range edge on decline in abundance, and found that species with range edges north of Concord, rather than near to Concord, were much more likely to have declined in abundance. This finding supports the notion that species decline is likely associated with shifting environments resulting from climate change rather than to a local range edge effect. Because species mean latitudinal range was found to be a much better predictor of decline in abundance when analyzed with species range edge, however, the latter was excluded from our analyses.

Native/Introduced Status. We obtained native/introduced status for each species from the U.S. Department of Agriculture PLANTS Database (45). Species were scored as "native" if they occurred in the continental United States or Canada at the time of Columbus, and "introduced" if they arrived from other regions since that time. A small number of species (11 species) were coded ambiguously as "native and probably introduced" and were not included in our analyses.

Phylogeny Construction. A composite phylogeny of all species was constructed with Phylomatic version 1 (46) and was further resolved above the generic level by using recently published molecular phylogenies. Studies using >1 gene were preferred, and bootstrap support >80% was required to resolve relationships. Branch lengths were scaled to be approximately equal to time with divergence time estimates aggregated in Phylocom version 3.41 by using the 'BLADJ' function (47). Our composite phylogeny with branch lengths scaled for time (www.huh.harvard.edu/research/staff/davis/fig.S2.pdf, references for composite phylogeny construction embedded in Fig. S1) is available on TreeBASE (www.treebase.org). Species were pruned from this tree as necessary depending on data availability for each analysis. To test the robustness of our results to uncertainties associated with divergence time estimation, we also ran our analyses on the same composite tree, but with branch lengths set to 1.

Phylogenetic Conservatism and Trait Correlations. The phylogenetic conservatism of each trait was evaluated separately by calculating the average magnitude of standard deviation (SD) of descendant nodes over the phylogeny, by using methods modified from Blomberg and Garland (48) as implemented in Phylocom by using the analysis of traits function (47).

Standard trait correlations can be biased by species relatedness (49, 50). To account for evolutionary history in trait correlations, we used the comparative method of generalized estimating equations (GEE; ref. 51), as implemented in APE version 2.1-3 (52). GEE incorporates a phylogenetic distance matrix into the framework of a general linear model. Importantly for this study, GEE also permits the simultaneous analysis of multiple categorical and continuous traits as covariates in the same model. The inclusion of covariates allowed us to control for the effects of other factors that are likely to have an impact on change in abundance, including initial abundance, habitat, native/introduced status, and flowering season.

We used 3 models to test for the correlation between change in abundance and our traits of interest (i.e., flowering-time tracking, flowering-time shift, and species latitudinal range). Model 1 tested for the effect of each trait (e.g., flowering-time tracking) on change in abundance:

$$\text{change in abundance} = \text{flowering-time tracking.}$$

Model 2 tested for the effect of each trait while accounting for the effects of a set of additional covariates that could also influence decline in abundance [i.e., initial abundance (ca. 1900), habitat, native/introduced status, and flowering season (date of first flowering)]:

$$\begin{aligned} \text{change in abundance} = & \text{flowering-time tracking} \\ & + \text{initial abundance} \\ & + \text{habitat} \\ & + \text{native/introduced status} \\ & + \text{flowering season.} \end{aligned}$$
